19. Abstract (continuation)

The three specific aims of this project include: 1) the characterization of the human and monkey photoreceptor lattice; 2) the study of new spatial discriminations in two-dimensions including circle center, area, and dot density discriminations, and 3) the expansion and generalization of current models of one-dimensional spatial discriminations such as spatial-frequency, line separation, and vernier acuity.

2180-88-47-4401A
We have digitized the cone centers of a primate and a human photoreceptor lattice (Hirsch and Miller, 1987, Hirsch and Curcio, 1987). Lattice disorder appears to have a deleterious effect on resolution beyond two degrees (Hirsch and Miller, 1987). Comparison of rod and cone capture areas shows compensatory influences factors between cone density and aperture size. We find that monkey and human photoreceptor lattices are not isomorphic. Rods intrude closer to the foveal center in humans than in monkeys, and cone density is higher in human fovea than in monkey fovea (Samy and Hirsch, 1988).

We have developed a new class of two-dimensional spatial discriminations, and have discovered that the center of a circle can be discriminated more accurately than the bisection of two points of comparable separation. This discovery has lead to the development of two additional lines of research, area discrimination and separation discrimination in a random dot display. We have identified a fundamental similarity between spatial-frequency discrimination and vernier acuity that demonstrates that Weber's Law applies similarly to both tasks (Hirsch and Groll, 1987). Further we have discovered that Weber's law predicts the fractional just-noticeable difference in discrimination of circle area (Groll and Hirsch, 1988). Further, we have shown that two-dot vernier discrimination falls off within two degrees of retinal eccentricity similarly to changes in retinal sampling (Groll and Hirsch, 1987). These findings contribute to a model of one-dimensional and two-dimensional spatial discriminations that includes limits imposed at the sampling level of the visual process.

We have recently expanded our approach to the study of one-dimensional spatial discriminations to include the question, "How long does it take for a spatial discrimination?", and have discovered that discrimination of high spatial-frequencies requires a shorter duration than low spatial-frequencies (Gallant and Hirsch, 1987). The overall goal of these three ongoing research aims is a comprehensive model of retinal sampling and spatial discriminations.

ANNUAL TECHNICAL REPORT

I. PROGRESS REPORT SUMMARY

The three specific aims of ^{this} ~~the~~ current ongoing project include: 1) the characterization of the human and monkey photoreceptor lattice; 2) the study of new spatial discriminations in two-dimensions including circle center, area, and dot density discriminations, and 3) the expansion and generalization of current models of one-dimensional spatial discriminations such as spatial-frequency, line separation, and vernier acuity. Each of these aims are currently active areas of research and are incorporated into the proposed research described in Section 2.

II. SPECIFIC AIMS OF CURRENT RESEARCH:

Aim 1: Photoreceptor Sampling

To measure the photoreceptor sampling array.

This aim includes determination of the foveal cone positional uncertainties associated with the photoreceptor sampling array of both monkey and human lattices. Various local and global indices of lattice quality including autocorrelation functions, radial and angular comparisons with a perfect lattice, and simulation of the lattice are also developed.

Aim 2: Two-Dimensional spatial discriminations

To study the accuracy with which observers can discriminate two-dimensional spatial variables.

Our studies of 2-D spatial discrimination tasks introduce a new type of spatial discrimination that expands the present models of spatial vision from one to two dimensions. We introduce area as a spatial variable, and measure the accuracy to which observers can locate the center of two-dimensional stimuli such as circles.

Aim 3: One-Dimensional spatial discriminations

To further develop and expand the scaled lattice model of spatial discrimination based on one-dimensional spatial tasks such as vernier, line separations, spatial-frequency discrimination and sampling properties of the foveal photoreceptor lattice.

This effort includes comparison of foveal vernier acuity and spatial-frequency performance, development of an interleaved paradigm to study the fine structure of spatial discrimination functions, application of a masking and temporal paradigm to study the influence of duration on one-dimensional spatial discrimination tasks, and measurement of two-dot vernier performance from the fovea out to approximately two degrees of retinal eccentricity to relate changes in the photoreceptor lattice structure to changes in vernier discrimination.

ANNUAL TECHNICAL REPORT

III PROGRESS ON AIM 1: PHOTORECEPTOR SAMPLING

A. Primate Lattice: Does cone positional disorder limit resolution?

We have measured the spacings between all cones in a strip of primate retina extending from the foveal center to approximately 5.75 temporal horizontal degrees of retinal eccentricity and in a circular window with a diameter of 1.0 degree. The strip is partitioned into 25 contiguous square windows and the circle is partitioned into six wedges. Positions of the cone centers in each lattice window are digitized for analysis of lattice structure and quality, and used to compare lattice properties at different retinal eccentricities and meridia. We find a monotonic increase in cone spacing with retinal eccentricity and meridional symmetry within the central one degree.

Further we demonstrate that estimates of center-to-center spacing vary with both window size and retinal location. Retinal sampling limits based on the sampling theorem and a correction for hexagonal packing are consistent with measures of human acuity along the same meridian from the foveal center to about 1.25 degrees of retinal eccentricity. Beyond about 1.25 degrees of retinal eccentricity these sampling boundaries overestimate human acuity. Lattice disorder, which is equivalent in its effect to increased receptor spacing, can account for the divergence of visual resolution and sampling limits from approximately 1.25 to 4.0 degrees of retinal eccentricity. Beyond 4.0 degrees of retinal eccentricity visual acuity may be additionally limited by other neural factors. (See Hirsch and Miller, 1987.)

B. Human Lattice: Does sampling by the Human Retina Predict Resolution?

Cone center-to-center spacings were determined on a strip of human retina extending from the foveal center along the temporal horizontal meridian to approximately 2.0 degrees of retinal eccentricity. The retina was obtained from a 35 year old male (H4 of Curcio et al., 1987) and has a cone density close to the average reported for young adults. A retinal whole mount (Curcio et al., 1987) was viewed with Nomarski differential interference microscopy at a level just vitreal to the ellipsoid-myoid junction. Positions of the cone centers were digitized from photomicrographs and the distributions of nearest-neighbor distances (Hirsch et al., 1984, 1987) were obtained for adjacent 0.165 deg² windows. We find an increase in receptor spacing over this 2.0 degree region that is similar to that previously reported for monkey and human. Application of the sampling theorem to these average spacing data identifies the Nyquist frequency, the highest spatial-frequency that can be unambiguously reconstructed by the retinal mosaic.

C. How do rod and cone capture areas compare for monkey and human retinas?

We have measured the photon capture areas associated with rod and cone photoreceptors at the ELM of both human and monkey retinal mosaics. Although cone density falls exponentially with eccentricity, i.e.

ANNUAL TECHNICAL REPORT

$$\text{cone density} = 53,184 \times x^{-0.66}$$

(where x is retinal eccentricity in degrees and density is specified in counts per mm^2), the retinal area subtended by the cone capture region falls approximately linearly with eccentricity. Cones occupy 100% of the capture area in the foveal region, and only approximately 75% of the area by about 6 degrees. Therefore, the fall-off in density is much faster than the fall-off in the capture area. This is due to the exponential increase in cone diameter with eccentricity:

$$\text{cone diameter } (\mu) = 4.7 \times x^{0.28}$$

(where x is retinal eccentricity in degrees), which compensates in part for the rapid reduction in density. Continuing efforts in the current proposal focus on understanding the structural dynamics of the retina and predictions for limits of visual sensitivity.

IV. PROGRESS ON AIM 2: 2-D SPATIAL DISCRIMINATIONS

A. Center Offset Discrimination is Better for Circles than for Two Dots with Comparable Diameters and Separations

We have compared discrimination of horizontal offset from the geometric center of circles and two-dot bisection stimuli. Center offset discrimination was measured for circles ranging in diameter from about 0.34 to 2.0 degrees and compared to two-dot bisection performance with dot separations equal to the circle diameters. We find that for small stimuli (diameter ≤ 0.5 degrees), just-noticeable-differences, jnds, in circle center offset Δc and jnds in two-dot bisection Δb are approximately equal. For larger stimuli, performance on the two-dimensional circle task progressively exceeds performance on the one-dimensional bisection task. A similar advantage is achieved for center offset discrimination of an ellipse when the horizontal diameter is set at 1.0 degree and the vertical diameter varies. We find that when the vertical diameter is smaller than about 0.5 degrees, the jnd in center offset Δe is equivalent to Δb for the comparable bisect task. For larger ellipses, Δe equals Δc for the comparable circle. Further we demonstrate that a two-dimensional stimulus can be degraded to as few as 4 dots with no deleterious effect on the center offset jnd. These results suggest that the human visual system is apparently able to exploit a two-dimensional spatial parameter, perhaps area, in order to achieve a discrimination advantage.

ANNUAL TECHNICAL REPORT

B. Area Discrimination

Continuing in the direction of Aim 2 we have developed an experimental paradigm to determine the jnd in circle area. Overall, Weber's Law describes one-dimensional discriminations in spatial-frequency, line separation and vernier acuity. However, no relationship has been described for discrimination of area. These experiments follow a similar discrimination paradigm as previously developed for one-dimensional discriminations (Hirsch and Hylton, 1982, 1984, 1985 and Groll and Hirsch, 1987), and will determine the $\Delta A/A$ for circles over a range of circle area, A.

C. Dot Density Discrimination

Discrimination of dot density, ΔD , provides a probe of human spatial information limits. We intend to determine $\Delta D/D$ over a range of reference densities, D, for various circle diameters and relate the discrimination function to the sampling limits of retina. These experiments will lead to a model of information efficiency based on sampling density.

V. PROGRESS ON AIM 3: 1-D SPATIAL DISCRIMINATIONS

A. A unifying model of vernier and spatial-frequency discrimination.

The jnd in vernier offset Δv falls off with decreasing two-dot separation s similarly to the jnd in spatial-frequency Δf with increasing reference frequency f . Overall vernier offset discrimination tends to be slightly lower (higher resolution) than spatial-frequency discrimination. The fractional resolution in two-dot vernier offset discrimination $\Delta v/s$ plotted against dot separation in deg^{-1} yields a function similar to fractional resolution in spatial-frequency $\Delta f/f$ plotted against reference f . We find that $\Delta v/s$ plotted against s is approximately constant for both tasks demonstrating that Weber's Law generally applies for both vernier offset discrimination and for spatial-frequency discrimination. These results suggest that resolution for both two-dot vernier offset and spatial-frequency discrimination may be mediated by common scaling mechanisms and constrain general models of one-dimensional spatial discriminations.

B. Two-dot vernier discrimination within 2.0 degrees of retinal fovea

We have studied two-dot vernier discrimination as a function of dot

ANNUAL TECHNICAL REPORT

separation at five retinal eccentricities between and including the fovea (0.0 degrees) and 2.0 degrees. We find an increase in the just-noticeable-difference, jnd, in vernier offset with retinal eccentricity and also an increase in the smallest dot separation at which the vernier task could be performed under our experimental conditions. Further, we find that the vernier just-noticeable-difference rises faster with eccentricity than the center-to-center distance between the photoreceptors. Thus as eccentricity increases from 0.0 to 2.0 degrees, progressively fewer hyperacuity level vernier jnds are measured. These data suggest that the limits of spatial discrimination are compromised beyond a very restricted central region of the fovea. (See Groll and Hirsch, 1987.)

C. Masking reduces separation and spatial-frequency discrimination more at larger than smaller spacing

We investigated the influence of temporal factors on line-separation and spatial-frequency discrimination using backward masking. In our procedure, each trial involved the sequential presentation of reference, test, and mask patterns. A 500 msec reference pattern was followed by a 500 msec delay and then by a 20 msec test pattern. After a variable interval, a 500 msec masking grating appeared. Fractional jnds ($\Delta s/s$ or $\Delta f/f$) were determined for reference separations and frequencies corresponding to 1, 4, 8, 12, and 16 cycles per degree. Each separation and frequency was examined over a range of test-mask temporal separation intervals from 20 to 100 msec. For all separations and spatial-frequencies tested, the fractional jnd increased as the interval between test and mask patterns decreased. However, the fall off in the fractional jnd depended upon separation or spatial frequency. The larger the separation (or lower the spatial frequency), the greater the deleterious effect on fractional jnd with masking. These results suggest that spatial discriminations require temporal exposures which covary with the size of the stimulus. (See Gallant and Hirsch, 1987.)

VI. SUMMARY AND OVERVIEW

We have digitized the cone centers of a primate and a human photoreceptor lattice and have determined the Nyquist limits to nearly six degrees of retinal eccentricity for monkey (Hirsch and Miller, 1987); and out to nearly two degrees for human (Hirsch and Curcio, 1987). Based on the primate lattice and the assumption that resolution is mediated by similar processes in both monkey and human, we find that lattice disorder appears to have a deleterious effect on resolution beyond two degrees (Hirsch and Miller, 1987). Comparison of rod and cone capture areas shows compensatory factors between cone density and aperture size (Samy and Hirsch, 1987). We have developed a new class of two-dimensional spatial discriminations, and have discovered that the center of a circle can be discriminated more

ANNUAL TECHNICAL REPORT

accurately than the bisection of two points of comparable separation (Hirsch and Groll, 1987). This discovery has led to the development of two additional lines of research, area discrimination and dot density discrimination. We have identified a fundamental similarity between spatial-frequency discrimination and vernier acuity that demonstrates that Weber's Law applies similarly to both tasks (Hirsch and Groll, 1987). Further, we have shown that two-dot vernier discrimination falls off within two degrees of retinal eccentricity similarly to changes in retinal sampling (Groll and Hirsch, 1987). These findings contribute to a model of one-dimensional spatial discriminations that includes limits imposed at the sampling level of the visual process. We have recently expanded our approach to the study of one-dimensional spatial discriminations to include the question, "how long does it take for a spatial discrimination?" and have discovered that discrimination of high spatial-frequencies requires a shorter duration than low spatial-frequencies (Gallant and Hirsch, 1987). The over-all goal of these three research aims is a comprehensive model of retinal sampling and spatial discriminations.
